Soil compaction frequently results from industrial disturbance on mineral soils, whether due to infrastructure or equipment traffic. Soil compaction tends to be most severe on sites with high clay content and high soil moisture, and when operations occur during non-frozen conditions. Natural processes such as freeze-thaw cycles are typically not enough to loosen deeply compacted soils (10–20 cm deep), in which case mechanical treatments will be required.
On sites with compacted soils, decompaction will be necessary to ensure trees can successfully establish and grow. Decompaaction breaks up the soil and improves water flow, aeration, nutrient accessibility, root growth and microsite availability (Fig. 1). However, as with all site preparation techniques, a vegetation management plan that includes weed management and seeding or planting will be critical to ensure that target species occupy the available microsites before competing vegetation.

**Figure 1. Decompaaction improves root growth and tree establishment.**

### Decompaacting a site

The appropriate decompaaction technique will depend largely on the characteristics of a reclaimed site, including clay content, soil moisture and the severity and depth of compaction (Table 1). The size and shape of a site will also affect the accessibility and maneuverability of equipment. A site assessment is a critical step for selecting the most effective decompaaction method(s) for a particular site (Fig. 2).
Figure 2 Decompaaction methods

**Winged subsoiler**
This pull-behind implement decompacts soil without inverting the topsoil. It creates large gaps that allow deep penetration of water into the soil, improving both soil moisture and further decompaction through freeze-thaw processes. It should not be used on very wet soils, as it will not break up clods effectively.

**Standard mounding**
Soil is scooped and placed in a mound adjacent to the newly created hole. This method is recommended for wet sites, as excavators are better able to access them, and the mounds create raised microsites favourable for plant growth.

**Straight ripper shank**
One or two vertically mounted shanks are pulled behind a dozer. This implement is most effective on dry soils with a low clay content and may be used to pre-treat extremely dry, compacted sites prior to using a winged subsoiler. Cross-ripping is recommended on sites that are severely compacted.

**Rough and loose mounding**
Soil is scooped and placed partially within the newly created hole. This approach creates a very heterogeneous soil surface.

Table 1. Primary soil decompaction methods and appropriate conditions for use.

Risks of decompaction

Decompaction equipment, timing and depths must be carefully planned to avoid damaging soils. The winged subsoiler, for example, will do little to break up soil clods in wet soils, and decompacting very dry soils increases the risk of mixing the topsoil with lower soil layers. Operations on wet, unfrozen soils may also cause additional soil compaction rather than alleviating it. Finally, decompaction must be planned in coordination with vegetation management, – seeding and/or planting, or the exposed microsites and mineral soil will be quickly overtaken by competing vegetation (Fig. 3).
